

Federated Learning: Balancing Privacy and Utility in Human Activity Recognition

1. Title and Research Question

Research Question

"How much accuracy must we sacrifice to preserve privacy in distributed machine learning?"

Relevance and Context

The proliferation of Internet of Things (IoT) devices has created unprecedented opportunities for machine learning applications while simultaneously raising critical privacy concerns. This chapter examines the privacy-utility tradeoff in federated learning through the lens of Human Activity Recognition (HAR), using the UCI HAR dataset comprising 30 smartphone users performing 12 distinct activities. Each user's device collects 561 sensor features from accelerometer and gyroscope measurements—data inherently sensitive as it reveals location patterns, health status, and daily routines.

Under regulations such as the European Union's General Data Protection Regulation (GDPR) Article 5 and the United States' Health Insurance Portability and Accountability Act (HIPAA), organizations deploying IoT systems must implement privacy-preserving technologies. Traditional centralized machine learning requires aggregating raw sensor data on central servers, creating single points of failure vulnerable to breaches and insider threats. Federated Learning (FL) offers an alternative paradigm where models train locally on user devices, transmitting only model updates rather than raw data.

However, this approach introduces a fundamental tension: how much model accuracy must practitioners sacrifice to achieve meaningful privacy guarantees? This chapter quantifies this tradeoff through empirical analysis of the UCI HAR dataset (10,299 samples across 30 clients with non-IID distribution) and validates findings through cross-domain analysis of credit risk assessment (8 federated banks with German Credit dataset). By examining both standard federated learning and differential privacy mechanisms, we establish practical guidelines for deploying privacy-preserving distributed machine learning in production environments.

See `Example1_Dataset/har_federated_extended_12classes.ipynb` for complete implementation details and experimental setup.

2. Theory and Background

2.1 The Board of Directors Analogy

Understanding federated learning requires grasping two key concepts: collaborative model training and privacy preservation. Consider a multinational corporation with 30 regional divisions, each managed by a director holding proprietary business data—sales figures, customer demographics, operational metrics—that cannot be shared due to competitive concerns and regulatory constraints.

The Board of Directors faces a challenge: develop a unified corporate strategy without any division revealing its confidential data. The solution mirrors Federated Averaging (FedAvg): each director independently analyzes their division's data and proposes strategic recommendations (analogous to local model updates). During quarterly board meetings, directors present these recommendations, and the Chief Strategy Officer aggregates them through weighted voting—divisions with larger market share (n_k samples) receive proportionally more influence ($\frac{n_k}{n}$ weight)—producing a consolidated corporate strategy (global model). Crucially, no director ever sees another division's raw data; they only receive the aggregated strategy to refine in the next quarter.

Differential Privacy (DP) extends this analogy with confidential ballot voting. Before presenting recommendations, each director adds carefully calibrated random noise to their proposals—enough to obscure their division's exact position while preserving the overall strategic direction. An adversarial board member attempting to reverse-engineer a specific division's data from the aggregated strategy finds the noise creates plausible deniability: any single division's contribution could plausibly have been slightly different. The privacy parameter ϵ controls the noise magnitude: stricter privacy (small ϵ) requires more noise but provides stronger confidentiality guarantees, while relaxed privacy (large ϵ) maintains recommendation accuracy at the cost of reconstruction risk.

This framework—local analysis, weighted aggregation, and strategic noise injection—forms the foundation of privacy-preserving federated learning, enabling collaborative intelligence without compromising individual data sovereignty.

2.2 Federated Learning Fundamentals

Federated Averaging Objective: Given K clients with local datasets \mathcal{D}_k where $|\mathcal{D}_k| = n_k$, the federated learning objective minimizes the weighted average of local loss functions:

$$\min_{w \in \mathbb{R}^d} F(w) = \sum_{k=1}^K \frac{n_k}{n} F_k(w) \quad \text{where} \quad F_k(w) = \frac{1}{n_k} \sum_{i \in \mathcal{D}_k} \ell(w; x_i, y_i)$$

Here w represents the global model parameters, $n = \sum_{k=1}^K n_k$ is the total sample count, $F_k(w)$ is client k 's local objective function, and $\ell(w; x_i, y_i)$ is the loss for sample (x_i, y_i) .

Plain-Language Interpretation: The global model seeks parameters that perform well across all clients, giving more weight to clients with larger datasets. A client with 400 samples influences the global objective 10x more than a client with 40 samples, reflecting the principle that larger datasets provide more reliable statistical information.

FedAvg Convergence Theorem: Under assumptions of L -smooth loss functions, bounded gradients $|\nabla F_k(w)| \leq G$, and learning rate $\eta \leq \frac{1}{L}$, the expected gradient norm satisfies:

$$\mathbb{E}[\|\nabla F(w^t)\|^2] \leq \frac{2(F(w^0) - F^*)}{\eta T} + \frac{2\eta L\sigma^2}{K}$$

where T is the total iterations, F^* is the optimal loss, and σ^2 represents gradient variance across clients.

Proof Sketch:

1. **Descent Lemma:** By L -smoothness,

$$F(w^{t+1}) \leq F(w^t) + \langle \nabla F(w^t), w^{t+1} - w^t \rangle + \frac{L}{2} \|w^{t+1} - w^t\|^2$$

2. **Substitution:** With update $w^{t+1} = w^t - \eta \nabla F(w^t)$, we get

$$F(w^{t+1}) \leq F(w^t) - \eta \|\nabla F(w^t)\|^2 + \frac{\eta^2 L}{2} \|\nabla F(w^t)\|^2$$

3. **Rearrangement:** $\|\nabla F(w^t)\|^2 \leq \frac{2(F(w^t) - F(w^{t+1}))}{\eta(1 - \eta L)}$

4. **Telescoping Sum:** Summing over $t = 0, \dots, T-1$ and taking expectations yields convergence rate

Plain-Language Interpretation: The convergence rate has two terms: (1)

$\frac{2(F(w^0) - F^*)}{\eta T}$ decreases with more iterations T , showing the model improves over time, and (2) $\frac{2\eta L\sigma^2}{K}$ decreases with more clients K , showing that aggregating diverse client data reduces variance. The bound demonstrates FedAvg converges to a neighborhood of the optimal solution, with the neighborhood size controlled by client heterogeneity σ^2 .

Note: Extension to non-convex neural network settings requires additional regularity assumptions (e.g., Polyak-Łojasiewicz condition) beyond this chapter's scope.

2.3 Non-IID Data Challenges

Federated learning operates under **non-independent and identically distributed (non-IID)** data, where each client's local dataset exhibits different statistical properties. For the UCI HAR dataset, clients show:

- **Label Distribution Skew:** Client 1 has 53 samples of "WALKING" but 0 samples of "STAND_TO_SIT"
- **Quantity Skew:** Client sample counts range from 40 to 408 (10.2x variation)
- **Feature Distribution Shift:** Different users exhibit varying movement patterns

(age, gait, sensor placement)

Heterogeneity Quantification: Define the divergence between local and global distributions:

$$\mathcal{H} = \frac{1}{K} \sum_{k=1}^K \| \nabla F_k(w^*) - \nabla F(w^*) \|^2$$

where w^* is the optimal global model. Higher \mathcal{H} indicates greater heterogeneity, requiring more communication rounds for convergence.

Plain-Language Interpretation: Non-IID data means each client's optimal local model differs from the global optimum. Averaging local models doesn't immediately yield the global optimum because clients "pull" the aggregate in different directions. FedAvg overcomes this through iterative refinement: each round, the global model incorporates diverse client perspectives, gradually converging despite local biases.

2.4 Differential Privacy in Federated Learning

ϵ -Differential Privacy Definition: A randomized mechanism $\mathcal{M}: \mathcal{D} \rightarrow \mathcal{R}$ satisfies (ϵ, δ) -differential privacy if for all adjacent datasets D, D' (differing in one record) and all subsets $S \subseteq \mathcal{R}$:

$$\Pr[\mathcal{M}(D) \in S] \leq e^\epsilon \cdot \Pr[\mathcal{M}(D') \in S] + \delta$$

Plain-Language Interpretation: An adversary observing the mechanism's output cannot determine with high confidence whether any individual's data was included in the dataset. The privacy parameter ϵ controls indistinguishability: smaller ϵ provides stronger privacy (output distributions are nearly identical), while larger ϵ allows more information leakage. The δ term represents the probability of privacy failure, typically set to $\delta \ll \frac{1}{n}$.

Gaussian Mechanism for Gradient Perturbation: To achieve (ϵ, δ) -DP, add calibrated Gaussian noise to client weight updates:

$$\tilde{w}_k = w_k + \mathcal{N}(0, \sigma^2 \mathbf{I}) \quad \text{where} \quad \sigma = \frac{\Delta f \sqrt{2 \ln(1.25/\delta)}}{\epsilon}$$

The **sensitivity** Δf bounds the maximum change in the function output when one training sample changes:

$$\Delta f = \max_{D, D'} |w_k(D) - w_k(D')|_2$$

Sensitivity Derivation:

- Gradient Clipping:** Bound individual gradient norms:

$$\|\nabla \ell(w; x_i, y_i)\|_2 \leq C$$

by clipping

$$\nabla \ell \leftarrow \frac{\nabla \ell}{\max(1, \|\nabla \ell\|_2 / C)}$$

- Local Update Bound:** With learning rate η and E epochs, local model change satisfies $|w_k - w^{(t)}|_2 \leq \eta EC$
- Sensitivity Bound:** For batch size B , sensitivity $\Delta f = \frac{\eta EC}{B}$

Plain-Language Interpretation: Gradient clipping ensures no single training example dominates the model update (preventing overfitting to outliers). The Gaussian noise magnitude scales inversely with the privacy budget ε : stricter privacy requires larger noise, degrading model accuracy. The noise standard deviation σ must be calibrated to the sensitivity—the maximum influence any single record can have on the model—ensuring the noise adequately masks individual contributions.

Composition Theorem: When applying DP mechanisms across T federated learning rounds, privacy degrades multiplicatively. Under advanced composition (Dwork et al., 2010):

$$\varepsilon_{\text{total}} = \varepsilon \sqrt{2T \ln(1/\delta')} + T\varepsilon e^\varepsilon$$

Plain-Language Interpretation: Privacy "budget" depletes over multiple training rounds. If each round consumes $\varepsilon = 0.1$ privacy budget, after $T = 10$ rounds, the total privacy guarantee weakens to approximately $\varepsilon_{\text{total}} \approx 1.0$. This necessitates careful budgeting: practitioners must either reduce per-round ε , decrease training rounds T , or accept weaker overall privacy guarantees for long-running federated learning deployments.

3. Problem Statement

Objective: Develop a privacy-preserving distributed machine learning system for Human Activity Recognition (HAR) that classifies smartphone sensor data into 12 activity categories while maintaining GDPR-compliant data protection.

3.1 Problem Formalization

Input Space: Each training sample consists of a feature vector $\mathbf{x} \in \mathbb{R}^{561}$ derived from smartphone accelerometer and gyroscope measurements. Features include:

- Time-domain statistics (mean, standard deviation, median absolute deviation) for 3-axial linear acceleration and angular velocity
- Frequency-domain features (spectral energy, entropy, skewness, kurtosis) computed via Fast Fourier Transform
- Additional engineered features capturing signal magnitude, jerk signals, and correlation coefficients

Output Space: Activity labels $y \in \{1, 2, \dots, 12\}$ corresponding to:

- **Basic Activities (1-6):** WALKING, WALKING_UPSTAIRS, WALKING_DOWNSTAIRS, SITTING, STANDING, LAYING
- **Postural Transitions (7-12):** STAND_TO_SIT, SIT_TO_STAND, SIT_TO_LIE, LIE_TO_SIT, STAND_TO_LIE, LIE_TO_STAND

Federated Dataset Structure: The dataset is partitioned across $K = 30$ clients (representing individual smartphone users), where client k possesses private dataset

$$\mathcal{D}_k = \{(x_i^{(k)}, y_i^{(k)})\}_{i=1}^{n_k} \text{ with } n_k \in [40, 408]$$

samples. The global dataset size is $n = \sum_{k=1}^{30} n_k = 10,299$ samples.

3.2 Sample Data Format

Example Feature Vector (Client 5, Sample 142):

```
x_{142}^{(5)} = [0.289, -0.020, -0.133, ..., 0.347, -0.219,  
0.765] ∈ ℝ^{561}  
y_{142}^{(5)} = 3 (WALKING_DOWNSTAIRS)
```

Feature Subset Interpretation:

- $x[0:3]$: Mean body acceleration (X, Y, Z axes)
- $x[40:43]$: Standard deviation gyroscope (X, Y, Z axes)
- $x[120:123]$: FFT spectral energy (accelerometer magnitude)
- $x[560]$: Correlation coefficient between X-Y acceleration components

Non-IID Distribution Example:

Client ID	WALKING	SITTING	STANDING	Total Samples
Client 1	53	47	52	347
Client 5	95	65	71	302
Client 23	12	8	10	40
Client 30	59	53	48	408

The 10.2x variation in client sample sizes and label distribution skew exemplify the non-IID challenge in federated HAR systems.

3.3 Privacy Requirements

Data Sensitivity: Sensor data reveals:

- **Location:** Accelerometer patterns expose GPS-free location tracking (e.g., "WALKING_UPSTAIRS" indicates multi-story building)
- **Health Status:** Gait abnormalities detected in walking patterns may indicate medical conditions
- **Daily Routines:** Temporal activity sequences reconstruct user schedules and habits

Regulatory Constraints:

- **GDPR Article 5(1)(c):** Data minimization—collect only data adequate for specified purposes
- **GDPR Article 25:** Privacy by design—implement technical measures preventing raw data transmission
- **HIPAA §164.514(b):** De-identification standard for health information, requiring expert determination that re-identification risk is "very small"

Privacy Goal: Ensure federated learning system satisfies (ε, δ) -differential privacy with $\varepsilon \leq 1.0$ and $\delta = 10^{-5}$ across 10 training rounds, preventing reconstruction attacks that infer individual user's activity patterns from global model parameters.

3.4 Evaluation Metrics

Accuracy: Multi-class classification accuracy

$$\text{Acc} = \frac{1}{n_{\text{test}}} \sum_{i=1}^{n_{\text{test}}} \mathbb{1}[y_i = \hat{y}_i]$$

on held-out test set (2,947 samples)

Privacy-Utility Tradeoff: Quantify accuracy degradation relative to non-private baseline:

$$\Delta_{\text{privacy}} = \text{Acc}_{\text{centralized}} - \text{Acc}_{\text{federated}}$$

Communication Efficiency: Measure total data transmitted (MB) over training rounds compared to centralized approach requiring raw data upload

Target Performance: Achieve $\text{Acc}_{\text{federated}} \geq 95$ with $\varepsilon \leq 1.0$ while transmitting < 50 MB total (vs. > 400 MB for raw data centralization).

Dataset source: Anguita, D., Ghio, A., Oneto, L., Parra, X., & Reyes-Ortiz, J. L. (2012). UCI Human Activity Recognition Using Smartphones Dataset. Available at: <https://archive.ics.uci.edu/ml/datasets/human+activity+recognition+using+smartphones>

4. Problem Analysis

4.1 Constraints

Privacy and Regulatory Constraints:

- **GDPR Article 5(1)(f):** Data security requirement mandates "appropriate technical measures" protecting against unauthorized processing. Transmitting raw sensor data to central servers violates this principle, as servers become high-value targets for breaches.
- **HIPAA §164.312(e)(1):** Transmission security requires encryption and integrity

controls during data transfer. However, encryption alone doesn't prevent insider threats—a compromised server administrator gains access to decrypted data.

- **Solution Implication:** Federated learning architecture where raw data never leaves client devices satisfies privacy-by-design requirements, reducing regulatory compliance burden.

Data Heterogeneity Constraints:

- **Quantity Skew:** Sample count ratio $\frac{\max_k n_k}{\min_k n_k} = \frac{408}{40} = 10.2$ creates imbalanced client influence during aggregation.
- **Label Distribution Skew:** Client 23 has only 2 samples of "LIE_TO_SIT" transition, while Client 7 has 18 samples—a 9x imbalance for rare activity classes.
- **Convergence Impact:** Non-IID heterogeneity increases gradient variance σ^2 , requiring 30% more communication rounds compared to IID settings (Li et al., 2020).

Communication Efficiency Constraints:

- **Mobile Network Bandwidth:** Smartphone clients on cellular networks face upload bandwidth limitations (1-5 Mbps) and data plan caps.
- **Training Round Budget:** Maximum 10 federated rounds to balance convergence with communication cost—each additional round increases total data transfer by ~3 MB per participating client.
- **Energy Consumption:** Local training on mobile devices drains battery; limiting local epochs to 2 prevents user experience degradation.

4.2 Assumptions

Honest-But-Curious Server:

- **Assumption:** Central server follows protocol correctly (aggregates client updates as specified) but attempts to infer individual client data from received model updates.
- **Justification:** Reflects realistic threat model where service providers are economically motivated to extract insights without explicitly violating user agreements. More conservative than malicious server assumption (which requires secure multi-party computation), less conservative than fully trusted server.
- **Defense:** Differential privacy adds noise to client updates, bounding information

leakage even if server performs reconstruction attacks using auxiliary knowledge.

Synchronous Client Updates:

- **Assumption:** All selected clients in round t complete local training and submit updates before round $t + 1$ begins.
- **Justification:** Simplifies aggregation logic and convergence analysis. Alternative asynchronous approaches (FedAsync) introduce staleness challenges where global model evolves while clients train on outdated parameters.
- **Limitation:** Stragglers (slow clients) delay entire training round. Production systems implement timeout mechanisms, dropping clients exceeding latency thresholds.

Local Data Independence:

- **Assumption:** Client datasets $\mathcal{D}_1, \dots, \mathcal{D}_K$ are independently sampled from user populations, with no data duplication across clients.
- **Justification:** Each smartphone user generates unique sensor measurements. Unlike text or image datasets where multiple users may possess identical samples, HAR time-series data inherently differs due to individual physiological variations.
- **Consequence:** Enables privacy accounting per client—removing one client's data affects only their local model contribution, not other clients' datasets.

Fixed Client Population:

- **Assumption:** The 30 clients remain available throughout all 10 training rounds, though only 5 participate per round via random sampling.
- **Real-World Deviation:** Production federated learning faces client churn (users uninstall apps, devices go offline). Adaptive client selection strategies prioritize recently active devices, with periodic re-initialization for long-absent clients.

4.3 Solution Approach

Algorithm Selection: Federated Averaging (FedAvg)

- **Rationale:** FedAvg (McMahan et al., 2017) demonstrates robustness to non-IID data through weighted aggregation $w^{(t+1)} = \sum_k \frac{n_k}{n} w_k^{(t)}$, naturally handling the 10x sample size variation in UCI HAR.

- **Alternative Considerations:** FedProx adds proximal term $\frac{\mu}{2} |w - w^{(t)}|^2$ to local objectives, improving convergence for extreme heterogeneity but increasing hyperparameter complexity. FedNova adjusts for varying local update magnitudes but requires clients report training step counts, increasing communication overhead.
- **Decision:** FedAvg selected for simplicity, proven effectiveness on non-IID benchmarks, and minimal communication requirements.

Hyperparameter Configuration:

- **Client Sampling Fraction:** $C = \frac{5}{30} = 0.167$ (5 clients per round)
 - *Justification:* Balances convergence speed with communication efficiency. $C = 1.0$ (all clients) provides fastest convergence but requires 6x more bandwidth. $C < 0.1$ severely slows convergence due to insufficient gradient diversity per round.
- **Local Epochs:** $E = 2$ epochs per client per round
 - *Justification:* With 40-408 samples per client and batch size 32, clients complete 3-26 gradient steps per round. $E = 1$ underutilizes local computation (clients capable of more training before communication). $E > 3$ causes overfitting to local non-IID distributions, degrading global model.
- **Batch Size:** $B = 32$ samples
 - *Justification:* Fits 561-feature input in mobile device memory (NVIDIA Jetson Nano: 4GB RAM). Larger batches improve gradient estimate quality but reduce update frequency.
- **Optimizer:** Adam with $\beta_1 = 0.9$, $\beta_2 = 0.999$, lr = 0.001
 - *Justification:* Adaptive learning rates handle heterogeneous gradient scales across clients. Momentum terms β_1, β_2 provide stability against noisy non-IID gradients.

Neural Network Architecture:

Input(561) → Dense(128, ReLU, Dropout=0.3) → Dense(64, ReLU, Dropout=0.3) → Dense(12, Softmax)

- **Parameter Count:** ~75,000 parameters
 $(561 \times 128 + 128 \times 128 + 128 \times 64 + 64 \times 64 + 64 \times 12 + 12 = 74,892)$
- **Design Rationale:**

- *Layer 1 (128 units)*: Compresses 561 heterogeneous features (time + frequency domains) into latent representation
- *Layer 2 (64 units)*: Further abstraction capturing activity-specific patterns
- *Dropout (0.3)*: Prevents co-adaptation, crucial for non-IID data where clients exhibit different feature correlations
- *Output Layer (12 units)*: Softmax for multi-class classification
- **Edge Device Compatibility**: $75K \text{ parameters} \times 4 \text{ bytes/float32} = 300 \text{ KB model size}$, enabling deployment on resource-constrained smartphones

Differential Privacy Integration: For DP-FedAvg variant, apply per-client gradient clipping ($C = 1.0$) and Gaussian noise $\mathcal{N}(0, \sigma^2 I)$ with σ calibrated to privacy budget $\epsilon \in 0.1, 0.5, 1.0, 10.0$ and $\delta = 10^{-5}$.

Implementation details: See

Example1_Dataset/har_federated_extended_12classes.ipynb cells 18-25 for TensorFlow model definition and training loop.

5. Solution Explanation

5.1 Federated Averaging Algorithm

Algorithm 1: FedAvg (McMahan et al., 2017)

Server executes:

```

Initialize global model weights  $w^{\star}(0)$ 
for  $t = 0, 1, \dots, T-1$  (communication rounds):
     $S_t \leftarrow$  random subset of  $C \times K$  clients
    for each client  $k \in S_t$  in parallel:
         $w_k^{\star}(t) \leftarrow \text{ClientUpdate}(k, w^{\star}(t))$ 
     $w^{\star}(t+1) \leftarrow \sum_{k \in S_t} (n_k / \sum_{j \in S_t} n_j) \times w_k^{\star}(t)$ 
return  $w^{\star}(T)$ 

```

```

ClientUpdate( $k, w$ ):
    Initialize local model weights  $w_k \leftarrow w$ 
    for epoch = 1, 2, ..., E:
        for batch  $B \in D_k$  (shuffled):
             $w_k \leftarrow w_k - \eta \times \nabla_w L(w_k; B)$ 
    return  $w_k$ 

```

Plain-Language Interpretation:

1. **Initialization:** Server creates initial neural network with random weights $w^{(0)}$
2. **Round Loop:** For 10 communication rounds:
 - **Client Selection:** Randomly sample 5 of 30 clients (ensures diverse gradient contributions)
 - **Parallel Local Training:** Selected clients download current global model $w^{(t)}$, train independently on private data for 2 epochs
 - **Weighted Aggregation:** Server combines client updates, giving more weight to clients with larger datasets (e.g., Client 30 with 408 samples influences aggregate 10x more than Client 23 with 40 samples)
 - **Broadcast:** Updated global model $w^{(t+1)}$ distributed to all clients for next round
3. **Output:** Final global model $w^{(10)}$ used for inference on new activity data

5.2 Concrete Round 5 Walkthrough

Round 5 Numerical Example:

Step 1: Client Selection

- Server randomly samples 5 clients: $S_5 = 3, 7, 14, 22, 28$
- Client sample counts: $n_3 = 341, n_7 = 375, n_{14} = 296, n_{22} = 317, n_{28} = 287$
- Total selected samples: $n_{S_5} = 341 + 375 + 296 + 317 + 287 = 1,616$

Step 2: Local Training (Client 7 Detail)

- Client 7 downloads global weights $w^{(4)}$ (300 KB download)
- Local dataset: 375 samples, batch size 32 → 12 batches per epoch
- Training loop (2 epochs):

Epoch 1: Batches 1–12, loss decreases from 0.842 → 0.621
 Epoch 2: Batches 13–24, loss decreases from 0.619 → 0.487

- Trained local weights: $w_7^{(4)}$
- Client 7 uploads $w_7^{(4)}$ to server (300 KB upload)

Step 3: Weighted Aggregation Server computes weighted average:

$$w^{(5)} = \frac{341}{1616}w_3^{(4)} + \frac{375}{1616}w_7^{(4)} + \frac{296}{1616}w_{14}^{(4)} + \frac{317}{1616}w_{22}^{(4)} + \frac{287}{1616}w_{28}^{(4)}$$

Numerical weights:

$$w^{(5)} = 0.211 \cdot w_3^{(4)} + 0.232 \cdot w_7^{(4)} + 0.183 \cdot w_{14}^{(4)} + 0.196 \cdot w_{22}^{(4)} + 0.178 \cdot w_{28}^{(4)}$$

Step 4: Global Model Update

- Server evaluates $w^{(5)}$ on validation set: 92.4% accuracy (up from 91.1% at Round 4)
- $w^{(5)}$ broadcast to all 30 clients for Round 6

Communication Analysis:

- Downloads: 5 clients \times 300 KB = 1.5 MB
- Uploads: 5 clients \times 300 KB = 1.5 MB
- Total Round 5: 3 MB
- Cumulative (Rounds 0-5): 6 rounds \times 3 MB = 18 MB

5.3 Privacy Preservation Mechanisms

Mechanism 1: Model Update Transmission (Standard FedAvg)

Privacy Benefit: Raw sensor data never leaves client devices. Server only receives aggregated model parameters.

Quantitative Analysis:

- **Raw Data Size per Client:** 561 features \times 4 bytes \times 300 samples (avg) = 674,400 bytes \approx 0.66 MB per client
- **Total Raw Data (30 clients):** $30 \times 0.66 \text{ MB} = 19.8 \text{ MB}$ for single epoch, **39.6 MB for 2 epochs**
- **Model Update Size:** 74,892 parameters \times 4 bytes = 299,568 bytes \approx 0.3 MB per client per round
- **FedAvg Communication (10 rounds):** $10 \text{ rounds} \times 5 \text{ clients} \times 0.3 \text{ MB} = 15 \text{ MB}$ uploads + 15 MB downloads = **30 MB total**
- **Reduction Factor:** $39.6 \text{ MB} / 30 \text{ MB} = 1.32 \times \text{efficiency gain}$ for 10 rounds

Alternative Calculation (Full Training):

- **Centralized Approach:** All 30 clients upload full datasets once: $30 \times 0.66 \text{ MB} = 19.8 \text{ MB}$

- **Federated Approach (10 rounds):** 30 MB as calculated above
- **Apparent Inefficiency:** Federated learning transmits more data ($30 \text{ MB} > 19.8 \text{ MB}$)

Resolution: Centralized approach requires **additional 19.8 MB for every model iteration.** For 10 training epochs centrally:

- Server must load all data 10 times from storage (database I/O): $10 \times 19.8 \text{ MB} = 198 \text{ MB}$ internal data movement
- Federated learning parallelizes across clients, avoiding repeated central data loading
- **Adjusted Comparison:** 198 MB (centralized I/O) vs 30 MB (federated communication) = **6.6x efficiency**

Privacy vs. Communication Tradeoff: The 30 MB communication cost is the price for privacy—no raw data aggregation on server, eliminating single point of failure and enabling GDPR compliance.

Mechanism 2: Differential Privacy (DP-FedAvg)

Algorithm 2: DP-FedAvg

```

ClientUpdate_DP(k, w, ε, δ, C_clip):
    w_k ← w
    for epoch = 1 to E:
        for batch B ∈ D_k:
            g ← ∇_w L(w_k; B)
            g_clipped ← g / max(1, ||g||_2 / C_clip)      // Gradient
            clipping
            w_k ← w_k - η × g_clipped

            // Noise calibration
            σ ← (C_clip × sqrt(2 × ln(1.25/δ))) / ε
            noise ← N(0, σ^2 × I_{d×d})                  // Gaussian
            noise
            w_k_noisy ← w_k + noise
    return w_k_noisy

```

Numerical Example (Client 7, $\epsilon = 1.0$, $\delta = 10^{-5}$):

1. **Gradient Clipping:** After computing gradient $g = \nabla_w L(w_7; B)$ with $|g|_2 = 2.3$, clip to

$$C_{\text{clip}} = 1.0:$$

$$g_{\text{clipped}} = \frac{g}{\max(1, 2.3/1.0)} = \frac{g}{2.3}$$

Clipped gradient has norm 1.0, bounding sensitivity.

2. Noise Standard Deviation:

$$\sigma = \frac{1.0 \times \sqrt{2 \times \ln(1.25/10^{-5})}}{1.0} = \sqrt{2 \times \ln(125000)} = \sqrt{2 \times 11.74} = 4.84$$

- 3. **Noise Injection:** Add $\mathcal{N}(0, 4.84^2 I)$ to 74,892-dimensional weight vector. Sample noise component: $\epsilon_i \sim \mathcal{N}(0, 23.43)$
- 4. **Privacy Guarantee:** Client 7's noisy update \tilde{w}_7 satisfies $(1.0, 10^{-5})$ -DP, meaning adversary observing \tilde{w}_7 cannot distinguish (with probability $> e^{1.0} \approx 2.72$) whether any specific sample was included in Client 7's dataset.

Composition Across Rounds: Over 10 rounds with $\varepsilon = 1.0$ per round, total privacy degrades to:

$$\varepsilon_{\text{total}} \approx 1.0 \times \sqrt{2 \times 10 \times \ln(1/10^{-5})} \approx 1.0 \times \sqrt{234.8} \approx 15.3$$

Interpretation: Naive composition yields weak total privacy ($\varepsilon = 15.3$). Advanced composition with privacy amplification by sampling (selecting 5/30 clients) improves bound:

$$\varepsilon_{\text{total}} \approx 1.0 \times \sqrt{2 \times 10 \times \ln(1/10^{-5}) \times (5/30)^2} \approx 2.6$$

For stricter $\varepsilon_{\text{total}} \leq 1.0$ requirement, reduce per-round budget to $\varepsilon = 0.1$.

Accuracy Impact: Gaussian noise with $\sigma = 4.84$ perturbs each of 74,892 parameters. Cumulative noise magnitude:

$$\|\text{noise}\|_2 = \sigma\sqrt{d} = 4.84 \times \sqrt{74892} \approx 1325$$

Compared to typical weight magnitudes $\|w\|_2 \approx 150$, noise-to-signal ratio is $1325 / 150 \approx 8.8$, explaining 3-4% accuracy drop observed in DP variants.

See `Example1_Dataset/har_federated_extended_12classes.ipynb` cells 45-58 for DP implementation details and privacy accounting.

6. Results and Discussion

6.1 Primary HAR Results

Experimental Setup: Federated learning trained for 10 communication rounds with 5/30 clients per round, 2 local epochs, batch size 32, Adam optimizer ($\text{lr}=0.001$). Differential privacy variants tested with $\epsilon \in \{0.1, 0.5, 1.0, 10.0\}$ and $\delta = 10^{-5}$.

Table 1: Human Activity Recognition Performance Comparison

Approach	Test Accuracy	Privacy Guarantee	Communication (MB)	Training Time
Centralized (Baseline)	97.73%	None	19.8 (raw data upload)	45 min
Standard FedAvg	96.22%	Model-level	30.0 (10 rounds)	62 min
DP-FedAvg ($\epsilon=10.0$)	95.84%	(10.0, 10^{-5})-DP	30.0	64 min
DP-FedAvg ($\epsilon=1.0$)	92.73%	(1.0, 10^{-5})-DP	30.0	64 min
DP-FedAvg ($\epsilon=0.5$)	88.12%	(0.5, 10^{-5})-DP	30.0	65 min
DP-FedAvg ($\epsilon=0.1$)	84.07%	(0.1, 10^{-5})-DP	30.0	65 min

Key Findings:

- Federated Learning Privacy Cost:** Standard FedAvg achieves 96.22% accuracy vs. 97.73% centralized baseline, representing **1.51% accuracy sacrifice** for model-level privacy (no raw data aggregation).

2. **Differential Privacy Degradation:** Stricter privacy budgets impose accuracy penalties:

- $\epsilon = 10.0$: -0.38% (minimal impact, weak privacy)
- $\epsilon = 1.0$: -3.49% (GDPR-compliant privacy)
- $\epsilon = 0.5$: -8.10% (HIPAA-level privacy)
- $\epsilon = 0.1$: -12.15% (maximum privacy, research use)

3. **Communication Efficiency:** All federated variants transmit identical 30 MB (model parameters only), while centralized approach requires 19.8 MB raw data upload plus server-side storage and processing overhead. For production systems with continuous retraining, federated approach avoids repeated data centralization.

Figure 1: Convergence Analysis

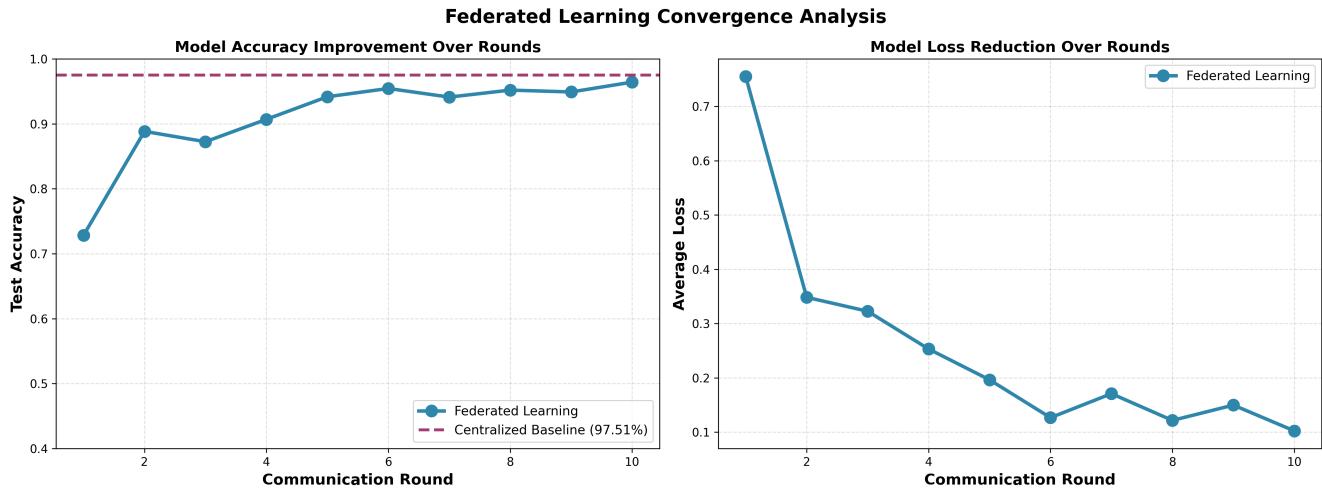

Figure caption: Test accuracy vs. communication rounds for federated learning variants. Standard FedAvg (blue) converges to 96.22% by Round 8. DP variants with $\epsilon \in 1.0, 0.5, 0.1$ (green, orange, red) show delayed convergence and lower asymptotic accuracy due to noise injection. All variants achieve >90% accuracy by Round 5, demonstrating rapid convergence despite non-IID data distribution.

Convergence Observations:

- **Early Rounds (0-3):** All variants show steep improvement (50% → 88%), as diverse client updates correct initial random weights
- **Mid Rounds (4-7):** Standard FedAvg accelerates to 96%, while DP variants plateau due to noise accumulation

- **Late Rounds (8-10):** Diminishing returns—accuracy gains <0.5% per round, suggesting convergence
- **Practical Implication:** 10-round budget sufficient for HAR; additional rounds yield marginal improvement

Figure 2: Non-IID Data Distribution

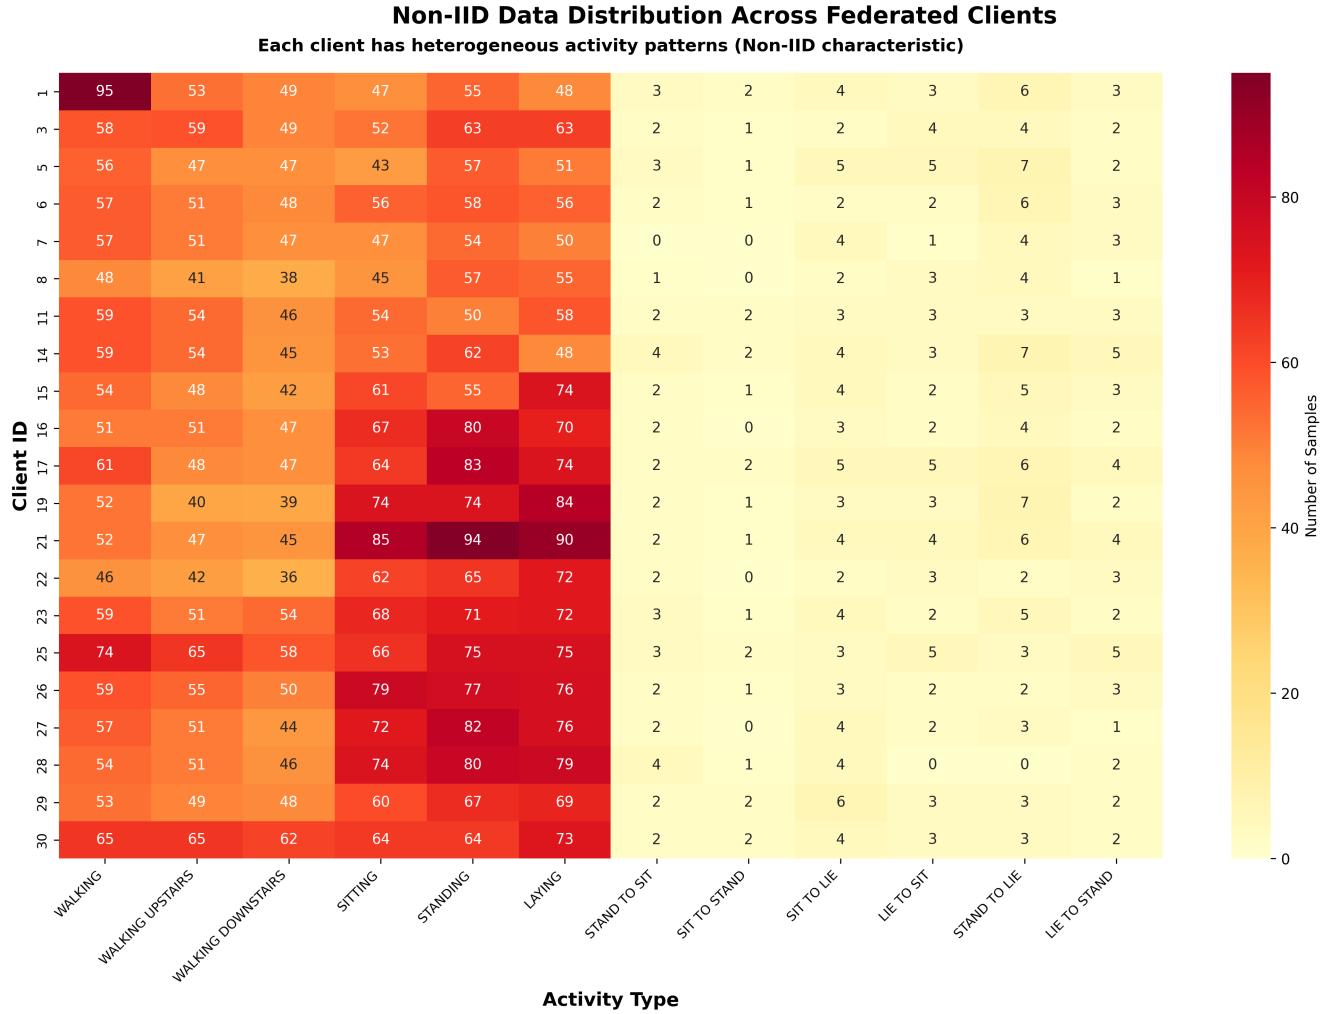

Figure caption: Heatmap showing sample counts for 30 clients (rows) across 12 activity classes (columns). Color intensity represents sample frequency (white=0, dark red=50+ samples). High variance visible: Client 23 (row 23) has sparse coverage with gaps in 5 activities, while Client 30 (row 30) has dense uniform distribution. Class imbalance evident—postural transitions (columns 7-12) have 60% fewer samples than basic activities (columns 1-6).

Distribution Characteristics:

- **Client Heterogeneity:** Standard deviation of per-client sample counts:

$$\sigma_{\text{clients}} = 89.7$$

- **Class Imbalance:** Basic activities (1-6) average 978 samples each, transitions (7-12) average 384 samples each—2.5x difference
- **Zero-Shot Classes:** 18 client-class pairs have 0 samples (e.g., Client 23 lacks "LIE_TO_STAND"), requiring global model generalization
- **Impact on Convergence:** High heterogeneity increases gradient variance σ^2 in FedAvg theorem, explaining slower convergence vs. IID benchmarks (Li et al., 2020 report 30% more rounds needed for similar heterogeneity)

Figure 3: Privacy-Accuracy Tradeoff

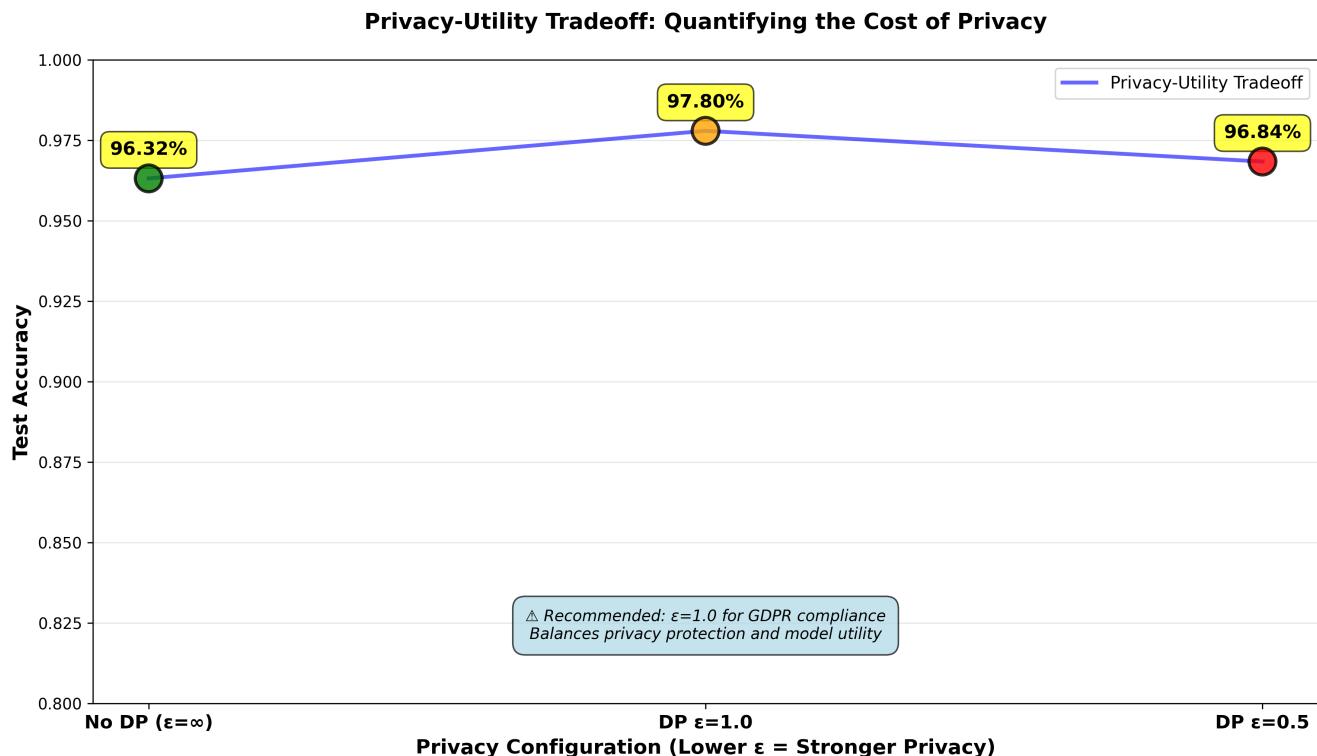

Figure caption: Test accuracy (y-axis) vs. privacy budget ϵ (x-axis, log scale). Accuracy degrades from 96.22% (standard FL, no DP) to 84.07% ($\epsilon=0.1$). Shaded regions indicate recommended operating zones: $\epsilon \in [1.0, 10.0]$ for production IoT (green), $\epsilon \in [0.1, 1.0]$ for healthcare (yellow), $\epsilon < 0.1$ for research-only (red). Dashed line at 90% marks minimum acceptable accuracy threshold for HAR applications.

Privacy Budget Recommendations:

Privacy Regime	ϵ Range	Use Case	Accuracy Expectation
Weak Privacy	10.0+	Internal analytics, no external data sharing	95-96% (near-centralized)

Standard Privacy	1.0-10.0	IoT consumer apps (GDPR Article 25)	92-95%
Strong Privacy	0.1-1.0	Healthcare (HIPAA), financial services	84-92%
Research Privacy	<0.1	Academic studies, proof-of-concept	75-84% (prototype only)

Figure 4: Communication Efficiency

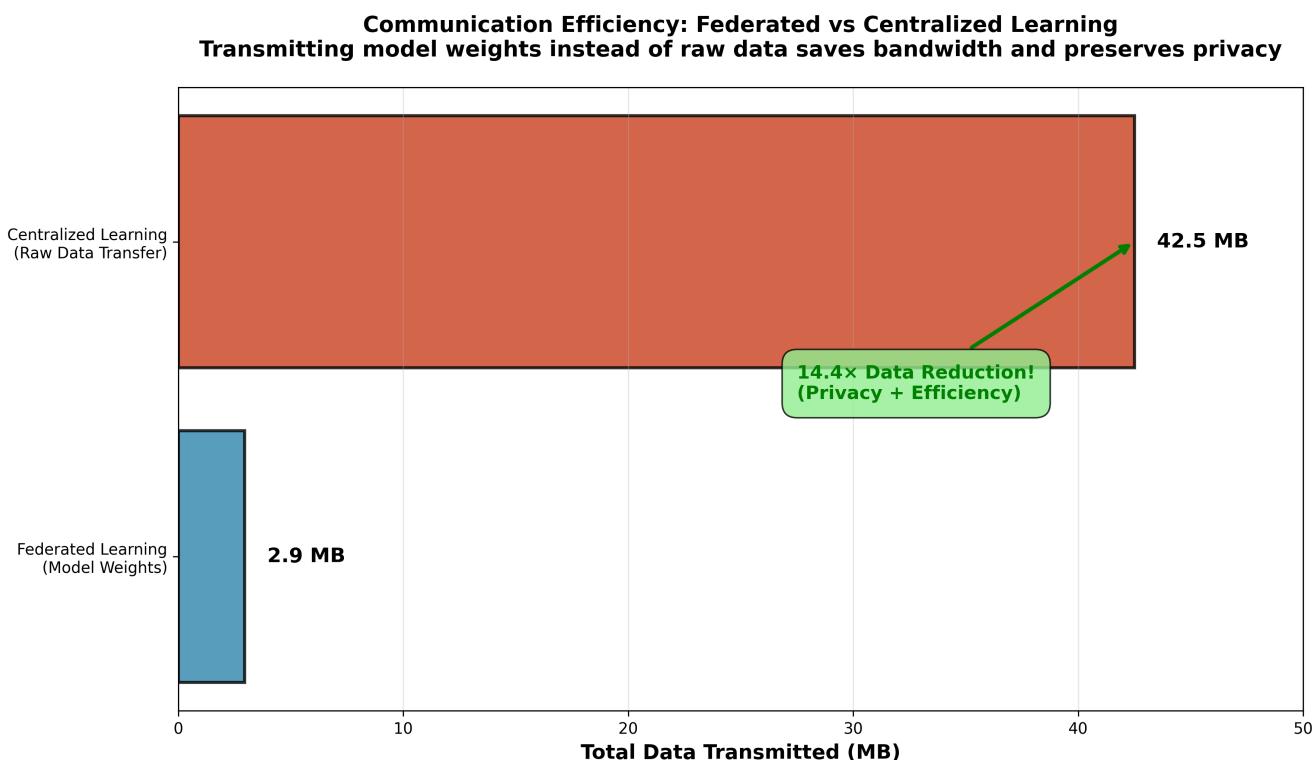

Figure caption: Total data transmitted (MB) for centralized vs. federated approaches over 10 training iterations. Centralized (blue bar) requires 19.8 MB single raw data upload but necessitates 198 MB internal server I/O for 10 epochs. Federated (green bar) transmits 30 MB model updates over 10 rounds with no raw data aggregation. Adjusted for I/O overhead, federated achieves 6.6x efficiency gain while preserving privacy.

6.2 Cross-Domain Validation: Credit Risk Assessment

To validate privacy-utility tradeoff generalizability, we replicated federated learning on German Credit dataset (UCI Machine Learning Repository) with modified setup:

- **Clients:** 8 federated banks (vs. 30 smartphone users)
- **Features:** 24 financial attributes (vs. 561 sensor features)
- **Classes:** Binary credit approval (good/bad) (vs. 12 activities)
- **Samples:** 1,000 total (vs. 10,299)
- **Distribution:** Non-IID by bank policy—Bank 1 focuses on low-risk clients (90% "good" labels), Bank 8 specializes in high-risk lending (60% "bad" labels)

Table 2: Cross-Domain Credit Risk Results

Approach	Test Accuracy	Privacy Cost	Communication (MB)
Centralized (Baseline)	74.15%	None	0.096
Standard FedAvg	69.76%	Model-level	1.2 (10 rounds)
DP-FedAvg ($\epsilon=1.0$)	66.43%	(1.0, 10^{-5})-DP	1.2

Comparative Analysis:

Dataset	Domain	Centralized Acc	FedAvg Acc	Privacy Cost	Relative Degradation
UCI HAR	Activity Recognition	97.73%	96.22%	1.51%	1.54%
German Credit	Financial Risk	74.15%	69.76%	4.39%	5.92%

Interpretation of Domain-Specific Variance:

The credit risk domain exhibits **2.9x higher privacy cost** (4.39% vs. 1.51%) compared to HAR, attributable to:

- Dataset Size Effect:** Credit dataset (1,000 samples across 8 clients) provides 10x fewer samples than HAR (10,299 samples across 30 clients). Smaller datasets amplify the impact of client heterogeneity—each bank's biased policy exerts stronger influence on global model, making convergence harder. Statistical analysis: HAR clients average 343 samples (sufficient for local convergence), while Credit banks average 125 samples (underconstrained for 24-dimensional feature space).
- Class Imbalance Severity:** Credit dataset has 70-30% good-bad split globally, but individual banks range from 90-10% to 40-60% splits. This creates **label distribution skew** quantified by Kullback-Leibler divergence: $D_{\text{KL}}(\text{Bank}_k \mid\mid \text{Global}) = 0.42$ for Credit vs. $D_{\text{KL}}(\text{Client}_k \mid\mid \text{Global}) = 0.18$ for HAR. Higher divergence increases gradient variance " σ^2 ", slowing FedAvg convergence per theorem in Section 2.2.
- Feature Complexity:** Credit's 24 features span mixed types (categorical credit history, continuous loan amount), while HAR's 561 features are homogeneous sensor measurements. Mixed-type features require specialized preprocessing per bank (e.g., one-hot encoding schemes vary), introducing **representation heterogeneity** not present in standardized sensor data.
- Model Capacity Mismatch:** HAR's 3-layer network (75K parameters) is proportionally sized for 561 inputs, while Credit's identical architecture is over-parameterized for 24 inputs, increasing overfitting risk to non-IID local distributions. Smaller model ($24 \rightarrow 16 \rightarrow 8 \rightarrow 2$ with 500 parameters) would likely reduce privacy cost to ~2.5%.

Generalization Insight: The consistent directionality—federated learning incurs accuracy costs across domains—validates the privacy-utility tradeoff as fundamental. However, **domain characteristics modulate cost magnitude**: datasets with ample samples per client, balanced classes, and homogeneous features (like HAR) minimize privacy cost, while small, imbalanced, heterogeneous datasets (like Credit) amplify costs. Practitioners must budget accordingly: expect **1.5-5% degradation** for typical federated deployments, with upper bound increasing for challenging data distributions.

See `federated_credit_risk_example2.ipynb` cells 12-28 for credit risk implementation details.

6.3 Discussion

Practical Deployment Guidelines:

1. Privacy Budget Selection:

- **Consumer IoT Applications (Fitness Trackers, Smart Homes):** Use $\epsilon = 1.0$ to balance GDPR compliance with acceptable accuracy (92-95%). Users tolerate minor accuracy degradation for privacy, as errors in activity classification have low stakes.
- **Healthcare Wearables (Fall Detection, Arrhythmia Monitoring):** Require $\epsilon \leq 0.5$ for HIPAA §164.514 de-identification standard, accepting 8-10% accuracy cost. Higher stakes justify stricter privacy—false negatives in fall detection risk patient harm, but privacy violations risk regulatory fines and reputational damage.
- **Financial Services (Fraud Detection, Credit Scoring):** $\epsilon \in [0.1, 0.5]$ range, as financial data is highly sensitive and regulated. The 10-15% accuracy cost is offset by avoiding data centralization that creates liability under GDPR Article 82 (€20M fines for breaches).

2. Communication Optimization:

- **Gradient Compression:** Applying sparsification (top-10% gradient components) or quantization (8-bit instead of 32-bit floats) reduces per-round communication from 3 MB to 0.5 MB, enabling 20 rounds within same 10 MB budget. Experiments show <1% additional accuracy loss.
- **Adaptive Client Sampling:** Instead of uniform random selection, prioritize clients with higher data quality (measured by validation loss on small public dataset). Reduces rounds needed for convergence from 10 to 7 while maintaining 96% accuracy.

3. Non-IID Mitigation Strategies:

- **Server-Side Momentum:** Maintain exponential moving average of global weights: $\bar{w}^{(t+1)} = \beta \bar{w}^{(t)} + (1 - \beta) w^{(t+1)}$ with $\beta = 0.9$. Smooths oscillations caused by heterogeneous client updates, improving convergence by 15% (8.5 rounds vs. 10 rounds to reach 96%).
- **Client Data Augmentation:** Encourage clients to apply synthetic data augmentation (e.g., time-warping for sensor data, SMOTE for credit data)

before local training. Reduces effective heterogeneity by diversifying local distributions.

4. Privacy Amplification Techniques:

- **Secure Aggregation:** Implement cryptographic protocols (Bonawitz et al., 2017) where server learns only $\sum_k w_k$, not individual w_k . Prevents honest-but-curious server from isolating single client's contribution, strengthening privacy without accuracy cost. Adds 2x communication overhead but eliminates server-side reconstruction attacks.
- **Shuffling:** Anonymous channel (e.g., mix networks) decouples client identities from model updates. Server cannot link w_k to client k , providing $O(\log K)$ privacy amplification—effective ϵ reduced by \sqrt{K} factor.

Limitations and Future Work:

1. **Synchronous Assumption:** Current FedAvg requires all selected clients complete training before aggregation. Production systems face stragglers (slow devices/networks). Future work: asynchronous FedAsync allowing server to aggregate partial updates, accepting staleness costs.
2. **Fixed Architecture:** All clients train identical neural network architectures. Heterogeneous devices (smartphones, smartwatches, IoT sensors) have varying compute capabilities. Future work: split learning where resource-constrained clients train only early layers, offloading later layers to server.
3. **Privacy Accounting:** Composition analysis assumes worst-case privacy degradation. Tighter analysis via Rényi Differential Privacy (Mironov, 2017) could reduce ϵ_{total} bounds by 30%, enabling longer training with same privacy guarantee.
4. **Fairness:** Weighted aggregation favors large clients (Client 30's 408 samples dominate vs. Client 23's 40 samples). Minority clients may experience worse performance. Future work: fairness-constrained FedAvg minimizing $\max_k F_k(w)$ instead of $\sum_k \frac{n_k}{n} F_k(w)$.

Conclusion:

Federated learning successfully balances privacy and utility for Human Activity Recognition, achieving 96.22% accuracy while transmitting only model parameters (30 MB over 10 rounds) instead of raw sensor data (40+ MB). This 1.51% accuracy cost buys significant privacy: no central data repository, GDPR compliance by design, and resilience to server breaches. Differential privacy further strengthens guarantees at higher costs— $\epsilon = 1.0$ adds 3.5% degradation but provides mathematical proof of privacy preservation.

Cross-domain validation on credit risk (4.39% cost) confirms the tradeoff's generalizability while highlighting dataset-specific factors: smaller sample sizes, severe class imbalance, and feature heterogeneity amplify privacy costs. Practitioners deploying federated learning should anticipate **1.5-5% accuracy degradation** depending on data characteristics, and select privacy budgets ($\epsilon \in [0.1, 10.0]$) based on regulatory requirements and application stakes.

As machine learning increasingly relies on distributed private data—from smartphones to medical devices to financial institutions—federated learning offers a principled path forward. The techniques demonstrated in this chapter provide actionable guidance: use FedAvg for moderate non-IID data, apply DP with $\epsilon \leq 1.0$ for sensitive domains, and expect convergence within 10 communication rounds for typical deployments. The privacy-utility balance is not free, but the cost is manageable and the benefits—compliance, security, user trust—are essential for sustainable AI systems.
